Abstract. The ABSTRACT MILLING problem is a natural and quite general graph-theoretic model for geometric milling problems. Given a graph, one asks for a walk that covers all its vertices with a minimum number of *turns*, as specified in the graph model by a 0/1 turncost function f_x at each vertex x giving, for each ordered pair of edges (e, f) incident at x , the *turn cost* at x of a walk that enters the vertex on edge e and departs on edge f . We describe an initial study of the parameterized complexity of the problem. Our main positive result shows that ABSTRACT MILLING, parameterized by: number of turns, treewidth and maximum degree, is fixed-parameter tractable. We also show that ABSTRACT MILLING parameterized by (only) the number of turns and the pathwidth, is hard for $W[1]$ — one of the few parameterized intractability results for bounded pathwidth.

1 Introduction

We consider the following problem:

ABSTRACT MILLING

Instance: A simple graph $G = (V, E)$ and for each vertex x , a *turncost function* f_x indicating whether a *turn* is required, with $f_x : E(x) \times E(x) \rightarrow \{0, 1\}$, where $E(x)$ is the set of edges incident on x .

Question: Is there a walk making at most k turns that visits every vertex of G ?

The GRID MILLING problem restricts the input to *grid graphs*, that is, rectilinearly plane-embedded graphs that are subgraphs of the integral grid, with the obvious and natural turn cost functions.

Results. Our basic starting point is an FPT algorithm for GRID MILLING, parameterized by the numbers of turns. Generalizing this, we give an FPT result for ABSTRACT MILLING, parameterized by (k, t, d) , where k is the number of turns, t is the tree-width of the input graph G , and d is the maximum degree of G . Next, we explore whether this positive result can be further strengthened. However: the ABSTRACT MILLING problem is $W[1]$ -hard when parameterized by (k, p) , where k is the number of turns and p is the path-width of G (and therefore also when parameterized by (k, t)). (This hardness result is actually shown for a restricted version of the problem, called DISCRETE MILLING, see below).

Significance. The ABSTRACT MILLING problem is motivated by (and generalizes) similar graph-theoretic models of geometric milling problems introduced by Arkin et al. [1], and our results are concretely interesting as the first investigation of the parameterized complexity of these problems. Recently, there has been increasing attention to the complexity of “highly structured graph problems” parameterized by treewidth or pathwidth. Our negative result provides one of the few natural problems known to be $W[1]$ -hard when the parameter includes a pathwidth bound.

Method and Practicality. Our FPT results are based on a general form of Courcelle’s Theorem about decidability of MSO properties of relational structures of bounded treewidth [2], and are not practical, although, of course leaving open the possibility that these FPT classifications may be superseded by practical FPT algorithms, as has often occurred in the study of fixed parameter algorithms [7].

Previous and Related Work. *Geometric milling* is a common problem in manufacturing applications such as numerically controlled pocket machining and automatic tool path generation; see Held [6] for a survey. The DISCRETE MILLING problem introduced by Arkin et al. [1] uses a graph model to study milling problems with turn costs and other constraints. A solution path must visit a set of vertices that are connected by edges representing the different directions (“channels”) that the “cutter” can take. In the model introduced by Arkin et al., incident edges to a vertex x are *paired* in the cost function f_x in the sense that for each incident edge e there is at most one incident edge f such that $f_x(e, f) = 0$, and symmetric: if $f_x(e, f) = 0$ then $f_x(f, e) = 0$. We consider here the more general ABSTRACT MILLING problem, that allows an arbitrary 0/1 turncost function at each vertex.

Arkin et al. [1] showed that DISCRETE MILLING is NP-hard (even for grid graphs) and described a constant-factor approximation algorithm for minimizing the number of turns in a solution walk. They also described a PTAS for the case where the cost is a linear combination of the length of the walk and the number of turns.

Definitions and Preliminaries. We will assume that the basic ideas of parameterized complexity theory and bounded tree-width algorithmics up through the basic form of Courcelle’s Theorem and monadic second-order logic (MSO) are known to the reader; some basic definitions are provided in Section 2 and in Appendix B. Details of routine deployments of MSO in the proofs of our theorems (that can be laborious in full formality) are relegated to Appendix A due to space limitations. For background on these topics, see [3, 5].

For a graph G , let $\text{tw}(G)$ be its treewidth. We assume that all graphs G are simple (no loops or multiple edges). A *walk* $W = [x_0, \dots, x_l]$ on a graph $G = (V, E)$ is a sequence of vertices such that every pair x_i, x_{i+1} of consecutive vertices of the sequence are adjacent (we use $x_i x_{i+1}$ to refer to the edge between them). The *turn cost* of a walk W is defined as

$$\text{tc}(W) = \sum_{i=1}^{l-1} f_{x_i}(x_{i-1}x_i, x_i x_{i+1}).$$

A walk that visits every vertex of a graph is termed a *covering walk*. Note that in ABSTRACT MILLING a solution covering walk may visit a vertex *many times*.

The paper is organized as follows: Section 2 reviews the basic ideas of MSO (and its extensions) that we need for proving our FPT results for GRID MILLING (Section 3) and ABSTRACT MILLING (Section 4). The intractability result for DISCRETE MILLING is shown in Section 5. We conclude with some open problems.

2 Monadic Second Order Logic

The usual MSO logic of graphs can be extended to digraphs and mixed graphs (some edges are oriented and some are not), where the vertices and edges (or arcs) have a fixed number of types. This was proved in full generality first by Courcelle [2], and is exposited well in [5] in terms of relational structures of bounded treewidth. We refer to such a mixed graph with a fixed number of types of edges, arcs and vertices as an

annotated graph. The treewidth of an annotated graph is the treewidth of the underlying undirected graph.

In this paper, we will associate to each input graph an annotated graph, in such a way that the property of being a yes-instance of the problem under consideration can be expressed as an MSO property of the associated annotated graph. The formal means that MSO logic (as we will use it here) provides us with, and Courcelle’s Theorem can be found in Appendix B.

3 Grid Milling is Fixed-Parameter Tractable

We prove here our starting point: that GRID MILLING is FPT for parameter k , the number of turns. We first argue that instances with large tree-width are no-instances. Then we show how to express the problem in (extended) MSO for an annotated graph $\mathcal{M}(G)$ that we associate to a GRID MILLING instance G . That is, we describe an MSO formula ϕ , such that the property expressed by ϕ holds for $\mathcal{M}(G)$ if and only if G is a yes-instance for the GRID MILLING problem.

Lemma 1. *Let $G = (V, E)$ be a connected grid graph with $\text{tw}(G) > 6k - 5$. Then G does not contain a $(k - 2)$ -turn covering walk.*

Proof. We show that G contains k vertices that have pairwise different x - and y -coordinates. Then, any covering walk needs to take at least one turn between any two such vertices, and thus it needs at least $k - 1$ turns in total.

Since G is planar and $\text{tw}(G) > 6k - 5$, by the Excluded Grid Theorem for planar graphs (c.f. [5]), it has a $(k \times k)$ -grid H as a minor. H contains $k/2$ vertex-disjoint nested cycles. Since taking minors can destroy or merge cycles but not create completely new ones, in the “pre-images” (under the operation taking minor) of these cycles there must be $k/2$ vertex-disjoint subgraphs in G , each containing a cycle. Thus, G contains a set $\mathcal{C}$ of $k/2$ vertex-disjoint cycles, which must also be nested. Consider a straight line L of unit slope that intersects the innermost cycle of $\mathcal{C}$ at two vertices (grid points). L must also intersect every other cycle at at least two vertices. This produces a set of at least k intersection vertices in G with the claimed property. $\square$

We associate to the grid graph G a (closely related) annotated graph $\mathcal{M}(G)$: we simply regard the horizontal edges as being of one type, and the vertical edges as being of a second type. Equivalently, we can think of G as presented to us with a partition of the edge set: $G = (V, E_h, E_v)$.

Then, intuitively, G has a k -covering walk if and only if there exist a start vertex v_0 , turn vertices $v_1, \dots, v_k$, an end vertex v_{k+1} , and sets of vertices $S_0, \dots, S_k$, such that:

- (i) the graph induced by S_i , $i = 0, \dots, k$, is a monochromatic path, i.e. a path whose edges are all either in E_h or in E_v ,
- (ii) the path induced by S_i starts at v_i and ends at v_{i+1} , and
- (iii) $V = \cup S_i$, i.e. all vertices of G are covered.

This is straightforwardly formalized in MSO (see Appendix A).

Lemma 2. *Let $G = (V, E_h, E_v)$ be a grid graph. The property of having a k -covering walk on G is expressible in MSO.*

Trivially, the model graph $\mathcal{M}(G)$ has treewidth bounded as a function of the treewidth of the original graph G . From Lemmata 1, 2 and Courcelle's Theorem we have:

Theorem 1. *GRID MILLING is FPT with respect to k (number of turns).*

4 Extending Tractability

What makes the GRID MILLING problem FPT? A few properties of grid graphs might lead us to tractable generalizations: (i) Yes-instances must have bounded treewidth, (ii) vertices in grid graphs have bounded degree, and (iii) the turn-cost function is pairing and symmetric, as in the more general DISCRETE MILLING problem.

We are naturally led to three questions, by relaxing these conditions:

- What is the complexity of ABSTRACT MILLING parameterized by (k, t, d) , where k is the number of turns, t is a treewidth bound, and d is a bounded on maximum degree?
- What is the complexity of DISCRETE MILLING parameterized by (k, t) ?
- What is the complexity of DISCRETE MILLING parameterized by (k, d) ?

In the remainder of this paper, we answer the first two. The third question remains open.

Theorem 2. *ABSTRACT MILLING is FPT for parameter (k, t, d) , where k is the number of turns, t the tree-width of the graph G and d is the maximum degree of G .*

Proof. We describe how an instance of the ABSTRACT MILLING problem, consisting of G and the turncost functions, can be represented by an annotated digraph $\mathcal{M}(G)$, that allows us to use MSO logic to express a property that corresponds to the question that the ABSTRACT MILLING

problem asks. The proof therefore consists of three parts: (1) a description of $\mathcal{M}(G)$, (2) some crucial arguments that establish necessary and sufficient criteria regarding $\mathcal{M}(G)$, for the instance of ABSTRACT MILLING to be a yes-instance, and (3) the expression of these criteria in MSO logic.

Let $G = (V, E)$ be the graph of the ABSTRACT MILLING instance. The vertex set of the digraph $\mathcal{M}(G)$ is $\mathcal{V} = \mathcal{V}_1 \cup \mathcal{V}_2$ where

$$\mathcal{V}_1 = \{l[v] : v \in V\} \quad \text{and} \quad \mathcal{V}_2 = \{t[e] : e \in E\} \cup \{t'[e] : e \in E\}$$

Intuitively (see Figure 1), we “keep a copy” of the vertex set V of G , mnemonically “ $l[v]$ ” for v , as a vertex location we might be during a solution walk in G . Each edge e of G is replaced by two vertices $t[e]$ and $t'[e]$ that represent a “state” in a solution walk: traversing e in one direction or the other. In order to distinguish the directions, consider that the vertex set V of G is linearly ordered. Let $e = uv \in E$ with $u < v$ in the ordering. Our convention will be that $t[e]$ represents a traversal of e from u to v , and that $t'[e]$ represents a traversal of e in the direction from v to u . Thus each edge e of G is represented by two vertices in $\mathcal{M}(G)$.

In describing arcs of the digraph model $\mathcal{M}(G)$ we will use the notation $x \cdot y$ to denote an arc from x to y . The arc set of the digraph $\mathcal{M}(G)$ is

$$\mathcal{A} = \mathcal{A}_1 \cup \mathcal{A}_2 \cup \mathcal{A}_3 \cup \mathcal{A}_4 \cup \mathcal{A}_5$$

where

$$\begin{aligned} \mathcal{A}_1 &= \{t[e] \cdot l[v] : e = \{u, v\} \in E \text{ with } u < v\} \\ \mathcal{A}_2 &= \{l[u] \cdot t[e] : e = \{u, v\} \in E \text{ with } u < v\} \\ \mathcal{A}_3 &= \{t'[e] \cdot l[u] : e = \{u, v\} \in E \text{ with } u < v\} \\ \mathcal{A}_4 &= \{l[v] \cdot t'[e] : e = \{u, v\} \in E \text{ with } u < v\} \end{aligned}$$

Let $\mathcal{A}'$ denote the union of these four sets of arcs. Intuitively, the arcs of $\mathcal{A}'$ just “attach” the vertices of the digraph that represent edges in G to the vertices of the digraph that represent the endpoints of the edge, so that the orientations of the arcs are compatible with the interpretation of a vertex of $\mathcal{V}_2$ as representing, say, a traversal of the edge uv in the direction from u to v ; the vertex therefore has an arc *to it* from $l[u]$ and an arc *from it* to $l[v]$. An inspection of Figure 1 will help to clarify.

The arc set $\mathcal{A}_5$ is more complicated to write down formally. Its mission is to record the possibilities for cost-free passages through vertices of a solution walk in G . Suppose a is an arc in $\mathcal{A}'$. Then a is *to* or *from* either

a $t[e]$ vertex, for some e , or a $t'[e]$ vertex for some e . Let $\epsilon(a)$ be defined to be this edge e of G . This is well-defined. We can then define

$$\mathcal{A}_5 = \{x \cdot y : x, y \in \mathcal{V}_2, \exists z = l[v] \in \mathcal{V}_1 \text{ and } \exists a, b \in \mathcal{A}' \\ \text{with } a = x \cdot z \text{ and } b = z \cdot y \text{ and } f_v(\epsilon(a), \epsilon(b)) = 0\}$$

We regard $\mathcal{M}(G)$ as an annotated digraph, in the sense that there are two kinds of vertices, those of $\sqsubseteq_1$ and those of $\sqsubseteq_2$, and two kinds of arcs, those of $\mathcal{A}'$ and those of $\mathcal{A}_5$.

Fig. 1. The arrows drawn near the G vertices represent the turncost functions, indicating the zero-cost possibilities. These become arcs in the digraph $\mathcal{M}(G)$.

The rest of the proof will show that the question of whether G admits a covering walk making at most k turns is represented by a property of the annotated digraph $\mathcal{M}(G)$ that can be expressed in MSO logic. However, before proceeding to that, it is important to verify that if the treewidth of G is bounded by t , then the treewidth of $\mathcal{M}(G)$ is bounded by a function of the parameter. This depends crucially on the fact that the maximum degree of G is part of our compound parameterization.

Suppose $\mathcal{T}(G)$ is a tree-decomposition of G of width at most t . We can describe a bounded width tree-decomposition $\mathcal{T}'$ of $\mathcal{M}(G)$ as follows. Without confusion, henceforth in this argument consider $\mathcal{M}(G)$ as an undirected graph by forgetting all arc orientations. Use the same bag-indexing tree for $\mathcal{T}'$ as for $\mathcal{T}(G)$. Suppose $B \subseteq V$ is a bag of $\mathcal{T}(G)$. Replace B with the union of the closed neighborhoods of the vertices of $\mathcal{V}_1$ corresponding to the vertices of B , in $\mathcal{M}(G)$. It is easy to check that all the axioms for a tree-decomposition hold, and that the treewidth of $\mathcal{M}(G)$ is therefore bounded by $2dt$.

In a digraph $D = (V, A)$, by a *purposeful set of arcs* (S, s, t) we refer to a set of arcs $S \subseteq A$, together with two distinguished vertices $s, t \in V$. We say that a purposeful set of arcs (S, s, t) is *walkable* if there is a directed walk W in D from s to t such that the set of arcs traversed by W (possibly repeatedly) is S .

Now consider how the information about G and its turncost functions is represented in $\mathcal{M}(G)$. A k -turn covering walk W in G that starts at a vertex s and ends at a vertex t is described by the information:

- (1) a sequence of $k + 2$ vertices: $s = x_0, x_1, \dots, x_{k+1} = t$, and
- (2) a sequence of $k + 1$ subwalks $W_0, \dots, W_k$ where for $i = 0, \dots, k$, W_i is a turncost-free walk from x_i to x_{i+1} , that has the property that every vertex of G is visited on at least one of the subwalks.

Let $\mathcal{D}(G)$ be the subdigraph of $\mathcal{M}(G)$ induced by the vertices of $\mathcal{V}_2$. A turncost-free walk in G corresponds to a directed walk in $\mathcal{D}(G)$, and vice versa, by the definition of $\mathcal{A}_5$.

Claim 1. G admits a k -turn covering walk if and only if:

- (1) there are $k + 2$ vertices $x_0, \dots, x_{k+1}$ of $\mathcal{V}_1$ in $\mathcal{M}(G)$, and
- (2) $k + 1$ purposeful sets of arcs (S_i, s_i, t_i) in $\mathcal{D}(G)$, $0 \leq i \leq k$, such that
 - (i) (S_i, s_i, t_i) is walkable in $\mathcal{D}(G)$ for $i = 0, \dots, k$,
 - (ii) there is an arc in $\mathcal{A}'$ from t_i to $x_{i+1} \in \mathcal{V}_1 = V$, and from x_i to s_i , for $i = 0, \dots, k$, and
 - (iii) for every vertex $x \in \mathcal{V}_1 = V$, there is some index j , $0 \leq j \leq k$, and an arc $a = u \cdot v \in S_j$, such that there is an arc in $\mathcal{A}'$ in either direction, between x and u or v .

In one direction, the claim is easy: given a k -turn covering walk W in G , it is naturally factored into $k + 1$ turncost-free subwalks W_i , and each traversal of an edge of G in a subwalk W_i corresponds in $\mathcal{M}(G)$ to a visit to a vertex of $\mathcal{V}_2$, thus the sequence of edge transversals of W_i in G corresponds 1:1 with a sequence $(y_0, \dots, y_{m+1})$ of vertices of $\mathcal{V}_2$ in $\mathcal{M}(G)$. Because W_i is turncost-free, by the definition of $\mathcal{A}_5$, there is an arc in $\mathcal{D}(G)$ from y_i to y_{i+1} for $i = 0, \dots, m$. We take the set of arcs to be S_i , $s_i = y_0$ and $t_i = y_{m+1}$, giving us (1) and (2) in a well-defined manner. It is straightforward to check that the conditions hold. For example, the assumption that W is a covering walk in G yields the last condition.

Conversely, suppose we have (1) and (2) in $\mathcal{M}(G)$. By the second condition, each S_i is walkable. By the definition of $\mathcal{A}_5$, a directed walk for S_i in $\mathcal{D}(G)$ corresponds to a turncost-free walk W_i in G . The third condition insures that the subwalks W_i in G can be sequenced into a

k -turn walk W , where the turns occur at the vertices x_i by the first condition. W is covering in G by the fourth condition, yielding Claim 1.

Claim 2. Consider a digraph $D = (V, A)$ equipped with distinguished vertices s and t (allowing $s = t$). The property: “there exists a directed walk from s to t that traverses (allowing repetition) every arc in A ” (that is, (A, s, t) is walkable) is expressible in MSO logic.

We first argue that (A, s, t) is walkable if and only if there is a directed path P in D from s to t , such that every arc $a \in A$ either is an arc of P , or belongs to a strongly connected subdigraph D_a that includes a vertex of P . We then argue (in Appendix A) that this property is expressible in MSO logic in a straightforward manner.

Given such a directed path $P = (s = x_0, \dots, x_m = t)$ in D , we can describe a walk W that traverses every arc of A as follows. By the *arcs of P* we refer to the set of arcs

$$A[P] = \{x_0x_1, x_1x_2, \dots, x_{m-1}x_m\}$$

The walk has m phases, one for each vertex x_i of the path P . Partition the arcs of $A - A[P]$ into m classes $A_0, \dots, A_m$ where for $i = 1, \dots, m$ every arc $a = uv \in A_i$ belongs to a strongly connected subdigraph D_a that includes the vertex x_i . Such a partition exists, by the supposed property of P . There is a directed path in D_a from x_i to u , and from v to x_i , by the strong connectivity of D_a , and so there is a directed cycle in D_a that includes both a and x_i . Include this cycle in W , starting from x_i and returning to x_i , for each arc $a \in A_i$. Increment i , take the arc from x_i to x_{i+1} and repeat this for $i = 0, \dots, m$.

Now suppose that there is a directed walk W in D from s to t that traverses every arc in A . If there is a vertex v that is visited more than once, then we can find a shorter walk W' that, considered as a sequence of arc transversals, is a subsequence of the sequence of arc transversals of W . Therefore, by downward induction, there is a directed path P from s to t , with no repeated internal vertex visits, that considered as a sequence of arc transversals, is a subsequence of the sequence of arc transversals of W . But then, every arc a traversed in the walk W (that is, every arc $a \in A$), that is not an arc of P , must belong to a subwalk W' of W that begins and ends at a vertex of P . The vertices visited by W' therefore induce a strongly connected subdigraph containing a vertex of P .

The second part of the proof of Claim 2 is to argue the property we have identified is expressible in MSO logic. This is fairly routine for MSO (see Appendix A). Based on Claims 1 and 2, the remainder of the proof of Theorem 3 is also straightforward (Appendix A). $\square$

5 Discrete Milling is Hard for Bounded Pathwidth

In this section, we see that the maximum degree restriction implicit in the parameterization for our positive result in the last section is one of the keys to tractability for this problem. Recall that in the DISCRETE MILLING problem the turncost functions are assumed pairing and symmetric. This is a significant assumption, but the outcome is still negative, and the following result very much strengthens, in the parameterized setting, the NP-completeness result of Arkin, et al. [1].

Theorem 3. DISCRETE MILLING is hard for $W[1]$, when parameterized by (k, p) , where k is the number of turns and p is a bound on pathwidth.

Proof. The fpt-reduction is from MULTICOLOR CLIQUE, using an edge representation strategy, such as described, for example, in [4, 8]. Suppose $G = (V, E)$ has V partitioned into color classes C_i , $i = 1, \dots, r$. The MULTICOLOR CLIQUE problem asks whether G contains a r -clique consisting of one vertex from each color class C_i . We can assume that each color class of G has the same size n [4]. The color-class partition of V induces a partition of E into $\binom{r}{2}$ classes $E_{\{i,j\}}$, for $1 \leq i \neq j \leq r$:

$$E_{\{i,j\}} = \{e \in E : \exists u \in C_i \text{ and } \exists v \in C_j \text{ with } e \text{ incident on } u \text{ and } v\}.$$

We can also assume that all these edge-partition classes $E_{\{i,j\}}$ have the same size m . We index the vertices and edges of G as follows:

$$\begin{aligned} C_i &= \{v(i, q) : 1 \leq q \leq n\} \quad \text{for } i = 1, \dots, r \\ E_{\{i,j\}} &= \{e(\{i, j\}, l) : 1 \leq l \leq m\} \quad \text{for } 1 \leq i \neq j \leq r. \end{aligned}$$

To refer to the incidence structure of G , we define functions $\pi_{\{i,j\}}^i(l)$ and $\pi_{\{i,j\}}^j(l)$ as follows:

$$\begin{aligned} \pi_{\{i,j\}}^i(l) &= q : \text{ the edge } e(\{i, j\}, l) \text{ is incident on } v(i, q) \\ \pi_{\{i,j\}}^j(l) &= q : \text{ the edge } e(\{i, j\}, l) \text{ is incident on } v(j, q), \end{aligned}$$

so the edge $e(\{i, j\}, l)$ is incident to $v(i, \pi_{\{i,j\}}^i(l))$ and $v(j, \pi_{\{i,j\}}^j(l))$.

We describe the construction of a graph G' , together with the sets S_v of turn-free pairs of edges for the vertices v of G' . We first describe the vertices of G' , and then specify a set of paths on these vertices. The edge set of the multi-graph G' is the (abstract) disjoint union of the sets of edges of these abstractly-defined paths, and it is understood that each

path is turn-free, so that (for the most part), the sets S_v of turn-free pairs of v -incident edges for the vertices v of G' are implicit in these *generating paths* of G' .

The vertex set V' for G' is the union of the sets $V_0 \cup V_1 \cup V_2 \cup V_3 \cup V_4$,

$$\begin{aligned} V_0 &= \{\sigma, \tau\} \\ V_1 &= \{t[i, j] : 1 \leq i \neq j \leq r\} \\ V_2 &= \{s[i, j] : 1 \leq i \neq j \leq r\} \\ V_3 &= \{c[i, j, u] : 1 \leq i \neq j \leq r, 1 \leq u \leq n\} \\ V_4 &= \{p[i, j, l] : 1 \leq i \neq j \leq r, 1 \leq l \leq m\}. \end{aligned}$$

Thus $|V_1| = |V_2| = 2\binom{r}{2}$, $|V_3| = 2n\binom{r}{2}$ and $|V_4| = 2m\binom{r}{2}$.

The edge set of G' is (implicitly) described by a generating set of paths $\mathcal{P}$ (two paths for each edge of G), together with a few more edges:

$$\mathcal{P} = \{P[i, j, e(\{i, j\}, l)] : 1 \leq i \neq j \leq r, 1 \leq l \leq m, \},$$

where the path $P[i, j, e(\{i, j\}, l)]$ (1) starts at the vertex $p[i, j, l]$; (2) next visits $s[i, j]$; (3) then visits the vertices $c[i, j, u]$, except for $u = \pi_{\{i, j\}}^i(l)$ (the *exceptional vertex* of this block), in *consecutive order*, meaning that the vertices are visited by increasing index u , modified by skipping the exceptional vertex; (4) then visits the vertex $c[i, j^*, \pi_{\{i, j\}}^i(l)]$, where j^* is defined to be $j + 1$, unless $j + 1 = i$, when $j^* = j + 2$, or $j = r$ and $i \neq 1$, when $j^* = 1$, or $j = r$ and $i = 1$, when $j^* = 2$; and then (5) ends at the vertex $t[i, j]$.

Intuitively, there are two paths in $\mathcal{P}$ corresponding to each edge of G . If we fix i and consider that there are $r - 1$ blocks of vertices (each block consisting of n vertices, corresponding to the vertices of C_i), then what a path $P[i, j, e(\{i, j\}, l)]$ (corresponding to the l^{th} edge of $E_{\{i, j\}}$) does is “hit” every vertex of its “own” $\{i, j\}^{th}$ block, except the vertex $c[i, j^*, \pi_{\{i, j\}}^i(l)]$ of the block corresponding to the vertex of C_i to which the indexing edge of G is incident, and in the “next block” in a circular ordering of the $r - 1$ blocks established by the definition of j^* , does the complementary thing: in this “next block” it hits *only* the vertex corresponding to the vertex of C_i to which the indexing edge is incident in G , and then ends at $t[i, j]$.

At this stage of the construction, the edges of G' are partitioned into (turn-free) paths that run between vertices of V_1 and vertices of V_4 , where the latter have degree 1 (so far) and the vertices of V_1 have degree m (so far). We complete the construction of G' by adding a few more edges, specifying a few more turn-free pairs as we do so.

(A) Add edges between the pairs of vertices $p[i, j, l]$ and $p[j, i, l]$ for all $1 \leq i \neq j \leq r$ and $1 \leq l \leq m$. After these edges are added, we have reached a stage where all vertices in V_4 have degree 2 (and they will have degree 2 in G'). For each vertex of V_4 we make the pair of incident edges a turn-free pair.

Note that for any instance of the DISCRETE MILLING, the edge set is naturally and uniquely partitioned into maximal turn-free paths. At this stage of the construction, these paths all run between $t[i, j]$ and $t[j, i]$ for $1 \leq i < j \leq r$.

(B) Add some edges between the vertices of $V_0 \cup V_1$. Let $\leq_{lex}$ denote the lexicographic order on the set (of pairs of indices) $\mathcal{I} = \{[i, j] : 1 \leq i < j \leq r\}$. Let $[i, j]^*$ denote the immediate successor of $[i, j]$ in the ordering of $\mathcal{I}$ by $\leq_{lex}$. For $[i, j] \in \mathcal{I}$, let $rev[i, j] = [j, i]$. We add the edges (using the notation $u \cdot v$ to denote the creation of an edge between u and v):

(B.1) $t[rev[i, j]] \cdot t[[i, j]^*]$ for $1 \leq i < j \leq r$ and $[i, j] \neq [r, r-1]$,

(B.2) $\sigma \cdot t[1, 2]$, and

(B.3) $t[r, r-1] \cdot \tau$.

We do not specify any further turn-free pairs of vertex co-incident edges beyond those specified in (A) or implicit by being internal to the generating paths $\mathcal{P}$ of G' . That completes the description of G' .

To complete the proof, we need to show that: (1) the graph G' will admit a k -turn covering walk, where $k = 2\binom{r}{2}$, if and only if G has a multicolor r -clique; and (2) G' has path-width at most $6\binom{r}{2} + 4$. (See Appendix A)

6 Open Problems

We have studied the parameterized complexity of (several versions of) the abstract milling problem with turn costs and gave an initial classification with respect to several parameterizations. Our FPT results are impractical, but can they be improved? In particular, it would be interesting to know if ABSTRACT MILLING parameterized by (k, t, d) admits a polynomial kernel. Our negative result provides one of the very few natural examples of a parameterized graph problem that is $W[1]$ -hard, parameterized by pathwidth. Another notable open question is whether DISCRETE MILLING parameterized by (k, d) , is FPT or $W[1]$ -hard.

Appendix A

Proof of Lemma 2:

Testing whether the graph induced by a set S of vertices is a monochromatic path in the grid graph G between two distinct vertices u and v of S can be done by the following formula:

$$\text{LinPath}(u, v, S) = \quad (1)$$

$$\left\{ \exists x : \langle Sx \wedge x \neq u \wedge Eux \rangle \wedge \langle \forall x' : (Sx' \wedge x \neq x' \wedge x \neq u) \rightarrow \neg Eux' \rangle \right\} \quad (2)$$

$$\bigwedge \left\{ \exists y : \langle Sy \wedge y \neq v \wedge Evy \rangle \wedge \langle \forall y' : (Sy' \wedge y \neq y' \wedge y' \neq v) \rightarrow \neg Evy' \rangle \right\} \quad (3)$$

$$\bigwedge \left\{ \langle \exists e = yx : (Sx \wedge Sy \wedge E_h e) \rangle \rightarrow \langle \forall e' = x'y' : (Sx' \wedge Sy') \rightarrow E_h e' \rangle \right\} \quad (4)$$

$$\bigwedge \left\{ \langle \exists e = yx : (Sx \wedge Sy \wedge E_v e) \rangle \rightarrow \langle \forall e' = x'y' : (Sx' \wedge Sy') \rightarrow E_v e' \rangle \right\} \quad (5)$$

$$\bigwedge \left\{ \forall S_1, S_2 : \langle \forall x : Sx \rightarrow [(S_1 x \leftrightarrow \neg S_2 x) \wedge (S_1 x \vee S_2 x)] \rangle \rightarrow \right. \quad (6)$$

$$\left. \langle \exists x_1, \exists x_2 : (S_1 x_1 \wedge S_2 x_2 \wedge E x_1 x_2) \rangle \right\}. \quad (7)$$

Lines (2), (3) assert that u and v have only one neighbor in S . Lines (4), (5) respectively check whether all the edges of G with both endpoints in S are horizontal or vertical (actually only one of the two lines is needed). Note that when no edge in G has both endpoints in S , both lines (3) and (4) become true, however this is taken care of by the next implication which checks connectivity. The implication (6) $\rightarrow$ (7) guarantees that for any bipartition (S_1, S_2) of S there is an edge from S_1 to S_2 , i.e. S induces a connected subgraph. Together with (2), (3), (4) and (5) this implies that the graph induced by S is a connected subgraph of G with either vertical or horizontal edges, where both u and v have degree one. Since G is a grid graph, each vertex has at most two horizontal and at most two vertical incident edges. Hence, the graph induced by S is a path with extremities u and v .

Finally, a k -covering walk exists if and only if there are $k+1$ subsets of vertices covering the vertex set of the input graph such that each induces a monochromatic path and such that these linear paths are joined end to end:

$$\Phi = \exists v_0, \dots, v_{k+1}, \exists S_0, \dots, S_k : \quad (8)$$

$$\left(\bigwedge_{0 \leq i \leq k+1} V v_i \right) \wedge \left(\forall v : V v \leftrightarrow \bigvee_{0 \leq i \leq k} S_i v \right) \wedge \left(\bigwedge_{0 \leq i \leq k} S_i v_i \right) \quad (9)$$

$$\wedge \left(\bigwedge_{0 \leq i \leq k} S_i v_{i+1} \right) \quad (10)$$

$$\wedge \left(\bigwedge_{0 \leq i \leq k} \text{LinPath}(v_i, v_{i+1}, S_i) \right) \quad (11)$$

□

Proof of Theorem 2: (MSO)

Let $D = (V, A)$ be a digraph, and s, t vertices of D (allowing $s = t$).

The first subtask (to finish the proof of Claim 2) is to describe an MSO predicate that expresses that there is a directed path P in D from s to t , quantified on the sets of vertices and arcs that form the path.

$$\text{dipath}(s, t) = \exists U(\subseteq V)\exists B(\subseteq A) : \dots$$

Where the remainder of the predicate expresses that in the subdigraph $D' = (U, B)$:

- s has outdegree 1 and indegree 0
- t has indegree 1 and outdegree 0
- every vertex of U not s or t has indegree 1 and outdegree 1
- for every partition of U into U_1 and U_2 such that $s \in U_1$ and $t \in U_2$, there is a vertex $u \in U_1$ and a vertex $v \in U_2$ with an arc in B from u to v

The formalization is completed in a very similar manner to the details of the proof of Lemma 2 (re: Linpath) above in this Appendix.

Being able to express that there is a directed path from s to t leads easily to an MSO predicate for strong connectivity of a subdigraph described by a set of vertices and a set of arcs.

An MSO predicate for *walkability* of a set of arcs A relative to s and t is easily (but somewhat tediously) constructed on the basis of the structural characterization of Claim 2, using the predicates for the existence of an s - t path, and for strongly connected subdigraphs.

An MSO formula to complete the proof of Theorem 3 is then trivial to construct by writing out Claim 1 in the formalism.

□

Proof of Theorem 3: (Correctness)

Figure 2 shows how the “coherence” gadgets for the reduction from MULTICOLOR CLIQUE work in our construction.

Suppose G' has a k -turn covering walk $\mathcal{W}$ that visits all the vertices of G' . (Recall that $k = 2\binom{r}{2}$.) Note that every visit to a vertex of $V_0 \cup V_1$ entails a turn. Since $|V_0 \cup V_1| = k + 2$, this implies that the walk $\mathcal{W}$ must begin and end at vertices of $V_0 \cup V_1$, and must visit each of the vertices in this set, internal to $\mathcal{W}$, exactly once. We can further conclude that we can view $\mathcal{W}$ as necessarily beginning at the vertex σ of G' and ending at the vertex τ , as otherwise, $\mathcal{W}$ would have to visit $t[1, 2]$ or $t[r, r - 1]$ more than once, in order to visit σ and τ .

Fig. 2. The choice and coherence gadgets for the reduction from MULTICOLOR CLIQUE. For this example, $r = 4$ and the vertex color classes C_i are called *red*, *blue*, etc.

Since the turns of the solution walk $\mathcal{W}$ occur (in each case exactly once) at the vertices of V_1 , we may conclude that $\mathcal{W}$ must consist of the edges added in (B), together with exactly $\binom{r}{2}$ maximal turn-free paths between $t[i, j]$ and $t[j, i]$ for $1 \leq i < j \leq r$. By the indexing of the paths in $\mathcal{P}$ in the construction of G' , $\mathcal{W}$ therefore corresponds to a set of $\binom{r}{2}$ edges of G , where for each i , exactly $r - 1$ of these edges are incident on a vertex of C_i . We must argue that, for a given i , these $r - 1$ edges of G are incident on *the same* vertex of C_i . (This is the job of what is sometimes called the *coherence gadget* for a reduction from MULTICOLORED CLIQUE using the edge-representation strategy — which we are employing here.) It is easy to check that the circularly interlocking path structure (for fixed i) of the paths in $\mathcal{P}$, together with the fact that the solution walk $\mathcal{W}$ visits all the vertices of V_3 (in particular, for the subset of V_3 formed by fixing i), insures that this is the case.

The converse direction is essentially trivial.

We next argue that the pathwidth of G' is bounded by a function of r . Let G'' be the subgraph of G' formed by deleting from G' the vertices of

$$V_0 \cup V_1 \cup V_2 \cup \{c[i, j, n] : 1 \leq i \neq j \leq r\}.$$

Note that we are deleting only the *last* vertices of the $2\binom{r}{2}$ blocks of n vertices (in each block) of the coherence gadgets of the construction (see Figure 2). The total number of vertices deleted is $6\binom{r}{2} + 2$. It is easy to check that G'' has pathwidth at most 2, and therefore G' has pathwidth at most $6\binom{r}{2} + 4$. $\square$

Appendix B

Parameterized complexity

A problem is *fixed-parameter tractable* with respect to a parameter k if it can be solved in $O(f(k) \cdot n^{O(1)})$ time, where n is the size of the input and f is a computable function depending only on k ; such an algorithm is (informally) said to run in *fpt-time*. The class of all fixed-parameter tractable problems is denoted by FPT. For establishing fixed-parameter intractability, a hierarchy of classes, the W-hierarchy, has been introduced: a parameterized problem that is hard for some level of W is not in FPT under standard complexity theoretic assumptions about the difficulty of quantified forms of the HALTING PROBLEM for nondeterministic Turing machines [3]. Hardness is sought via *fpt-reductions*: an *fpt-reduction* is an *fpt-time* Turing reduction from a problem Π , parameterized with k , to a problem Π' , parameterized with k' , such that $k' \leq g(k)$ for some computable function g .

Tree decompositions and graph minors

Definition 1. A tree decomposition of a graph $G = (V, E)$ is a pair $(T, \mathcal{X})$, where T is a tree and $\mathcal{X}$ is a family of subsets (bags) of V such that: 1) for any vertex $x \in V$, there exists $X \in \mathcal{X}$ such that $x \in X$; 2) for any edge $e = (x, y) \in E$, there exists $X \in \mathcal{X}$ such that $\{x, y\} \subseteq X$; and 3) for any vertex $x \in V$, the set of bags containing x induces a subtree T_x of T . The tree-width of a graph is:

$$tw(G) = \min_{(T, \mathcal{X})} \max_{X \in \mathcal{X}} (|X| - 1).$$

The notions of path decomposition and path-width are defined similarly by changing the tree T in the above definition to a path P . The path-width of a graph is always larger than or equal to its tree-width. Computing the tree-width of a graph G is NP-hard, but deciding whether the tree-width of G is at most k (and computing a tree-decomposition of width at most k in the positive case) is fixed-parameter tractable (c.f. [5]).

For an edge $e = xy$ of a graph G , contracting e results in replacing the vertices x and y , whose neighborhoods are denoted by $N(x)$ and $N(y)$ respectively, by a new vertex z whose neighborhood is $N(x) \cup N(y)$, excluding x and y . A graph H is a *minor* of a graph G if H can be obtained from G by a series of edge or vertex removals and edge contractions.

Monadic second order logic

MSO logic for annotated graphs gives us:

- variables denoting individual vertices ($s, t, u, v, \dots$, possibly with subscripts) and variables denoting sets of vertices ($S, T, U, V, \dots$, possibly with subscripts). We will use the notation Tt to denote that the vertex t belongs to the set of vertices T , and similarly in general.
- variables denoting individual arcs and edges ($a, b, \dots, e, f, \dots$) and sets of arcs and edges ($A, B, \dots, E, F, \dots$)
- logical quantification over these variables, logical connectives ($\wedge, \vee, \implies, \iff, \neg, \dots$) and equality ($u = v, E = F, \dots$)
- predicates ($inc(e, u), adj(u, v), in(a, u), out(a, v), \dots$) indicating incidence of edges and vertices, and arcs entering or leaving vertices
- predicates such as $A_r a$ (a is an arc of type r) and shorthands such as $\exists a = uv$ (there exists an arc a from u to v).

Theorem 4 (Courcelle [2]). *Any property of annotated graphs that can be expressed in MSO, is linear-time, finite-state recognizable for annotated graphs where the treewidth of the underlying graphs is bounded.*
